ABSTRACT

We investigate the impact of U.S. bombing on later economic development in Vietnam. The Vietnam War featured the most intense bombing campaign in military history and had massive humanitarian costs. We use a unique U.S. military dataset containing bombing intensity at the district level ($N = 584$) to assess whether the war damage led to persistent local poverty traps. We compare the heavily bombed districts to other districts controlling for district demographic and geographic characteristics, and use an instrumental variable approach exploiting distance to the 17th parallel demilitarized zone. U.S. bombing does not have negative impacts on local poverty rates, consumption levels, infrastructure, literacy or population density through 2002. This finding indicates that even the most intense bombing in human history did not generate local poverty traps in Vietnam.

1. Introduction

The horrors inflicted by war are clear to all, and so are its disruptive effects for people's lives. Indeed, war displaces population, destroys capital and infrastructure, disrupts schooling, and can produce negative environmental impacts, damage the social fabric, endanger civil liberties, and create health and famine crises. Any of these effects could be argued to have impacts on later economic growth and development, and their combined effects even more. Jean Drèze for one forcefully expresses the view that “[w]ars or rather militarism is the major obstacle to development in the contemporary world” (Drèze, 2000: 1171).

Yet the net long-run effects of war are unclear a priori. Poverty trap models of the kind developed by Azariadis and Drazen (1990), and recently promoted among policymakers by World Bank (2003) and Sachs (2005), predict that sufficiently severe war damage to the

capital stock could lead to a “conflict trap” that condemns an economy to long-term underdevelopment. Standard neoclassical growth theory yields different predictions regarding the effect of war on long-run economic performance. To the extent that the main impact of war is the destruction of existing physical capital and temporary reduction of human capital accumulation, neoclassical models predict rapid postwar catch-up growth as the economy converges back to its steady-state growth rate, resulting in no long-run impact. At the same time, war may also profoundly affect the quality of institutions, technology, and social outcomes. These institutional effects of war may in turn have negative or positive impacts on long-run economic performance. For instance, it is often argued that military research and development leads to faster technological progress, which may offset war damage. Wars may also promote state formation and nation building as was the case in Europe (Tilly, 1975), and may induce social progress via greater popular participation (Keyssar, 2000) or break the power of entrenched groups that block growth-promoting policies (Olson, 1982).

There is now a large literature, both theoretical and empirical, on the causes of armed conflict (see e.g. Fearon, 1995; Fearon and Laitin, 2003; Collier and Hoeffler, 1998, 2004; Powell, 2004) but the long-run economic impacts of war remain largely unexplored empirically (as

discussed in Blattman and Miguel, 2010), and this is so for several reasons. One important issue is the difficulty of convincingly identifying war impacts on economic growth in the presence of dual causality between violence and economic conditions, and possible omitted variable biases (Miguel et al., 2004). But a perhaps even more fundamental constraint for empirical work is the lack of data on war damage and economic conditions in conflict and post-conflict societies.

In this paper we exploit a data-rich historical episode to estimate bombing impacts on long-run economic performance, the U.S. bombing of Vietnam (what Vietnamese call “the American War”). The Indochina War, centered in Vietnam, was the most intense aerial bombing episode in history (Clodfelter, 1995):

“The United States Air Force dropped in Indochina, from 1964 to August 15, 1973, a total of 6,162,000 tons of bombs and other ordnance. U.S. Navy and Marine Corps aircraft expended another 1,500,000 tons in Southeast Asia. This tonnage far exceeded that expended in World War II and in the Korean War. The U.S. Air Force consumed 2,150,000 tons of munitions in World War II — 1,613,000 tons in the European Theater and 537,000 tons in the Pacific Theater — and 454,000 tons in the Korean War.”

Vietnam War bombing thus represented at least three times as much (by weight) as both European and Pacific theater World War II bombing combined, and about fifteen times total tonnage in the Korean War. Given the prewar Vietnamese population of 32 million, U.S. bombing translates into hundreds of kilograms of explosives per capita, more than the entire weight of the Vietnamese nation. For another comparison, the atomic bombs dropped at Hiroshima and Nagasaki had the power of roughly 15,000 and 20,000 tons of TNT, respectively (Grolier, 1995). Since general purpose bombs – by far the most common type of bomb used in Vietnam – are approximately 50% explosive material by weight, each atomic bomb translates into roughly 30,000 to 40,000 tons of such munitions. Measured this way, U.S. bombing in Indochina represents roughly 100 times the combined impact of the Hiroshima and Nagasaki atomic bombs.

We employ an unusual United States military district-level dataset on bombs, missiles, rockets and other ordnance dropped in Vietnam. The U.S. bombing of Vietnam was largely concentrated in a subset of regions: roughly 70% of total ordnance was dropped in only 10% of the 584 sample districts. Fig. 1 highlights the 10% most heavily bombed districts.

The heaviest bombing took place in Quang Tri province in the central region of the country near the 17th parallel, the former border between North Vietnam and South Vietnam. The province is the geographic unit above the district. Quang Tri province was basically bombed flat during the war, with most of its capital and infrastructure destroyed: only 11 of 3500 Quang Tri villages were left unbombed by the end of the war (Project RENEW Report, 2004: 3). Provinces immediately north and south of Quang Tri also received heavy U.S. bombing, although less than Quang Tri itself. Coastal regions of North Vietnam and some districts of Hanoi were heavily bombed, as was the region near Saigon adjacent to Cambodia. This region was the site of frequent incursions by North Vietnam Army and NLF/Vietcong troops into South Vietnam through the so-called Ho Chi Minh Trail that ran through Laos and Cambodia.

There are many a priori reasons U.S. bombing could have long-run impacts on Vietnamese economic development. First, the destruction of local physical infrastructure may have inhibited commerce and changed later investment patterns. For instance, U.S. bombing during the Rolling Thunder campaign of the late 1960s “destroyed 65 percent of the North’s oil storage capacity, 59 percent of its power plants, 55 percent of its major bridges” (Clodfelter, 1995: 134).² Second, U.S.

Fig. 1. Map of Vietnam – 10% of districts with the highest total U.S. bombs, missiles, and rockets per km² shaded.

bombing displaced population and this could potentially have reduced local economic activity if many individuals never returned. Third, population displacement and the destruction of physical infrastructure – including classrooms – disrupted schooling for millions, affecting human capital accumulation. In terms of other possible factors, we do not have complete information on unexploded ordnance (UXO), landmines or Agent Orange use, and unfortunately cannot focus on these in the main empirical analysis (however, there is obviously a strong correlation between bombing and later UXO density).³ Vietnam in the 1960s and 1970s was a society where one might intuitively expect a poverty trap model to be quite empirically relevant: at the start of the war in the 1960s, Vietnam was already one of the world’s poorest countries, and it was subject to massive devastation by American bombs, pushing income levels even lower. By the late 1970s, Vietnamese per capita income was comparable to that in the poorest African countries.

We compare the predictions of the neoclassical Solow growth model to a modified theoretical framework including a poverty trap in analyzing the long-run impacts of bombing Vietnam. In the neoclassical

³ UXOs as well as landmines can impair the use of agricultural land and are expensive to find and remove. While UXOs and landmines can seriously hurt farming families when an income earner is victimized, UXO and landmine injury rates in Vietnam during the 1980s and 1990s declined rapidly relative to the immediate postwar years (Project RENEW report, 2004: 16–18). The chemical agents used by the U.S. could also generate long-term damage to population health and land. The best known, Agent Orange, is a defoliant containing dioxins, and as late as 2001 traces of dioxins specific to Agent Orange were still found in human blood in some areas. Deforestation itself could also negatively affect the environment and agriculture by increasing soil instability and affecting wildlife.

² See Tilford (1991: 155) for further details on the extent of U.S. bombing damage.

model, a heavily bombed region eventually returns to steady-state economic performance despite the initial destruction of its capital stock. In contrast, if the bombing shock makes the region “too poor” to save and invest, a poverty trap model would predict that a region's income per capita would be permanently depressed. In that case, one would predict economic divergence between regions that were bombed heavily and those that were not. However, there will be no inter-regional economic divergence if there is sufficient factor mobility across regions of a country. There would be no regional poverty traps, or a poverty trap at the level of the country, but in either case we would not observe inter-regional divergence. Poverty traps can also be averted by government redistribution of capital towards poorer regions, lifting them above the poverty trap threshold, and thus ultimately generating sustained saving, investment and growth.

We then perform tests of the impact of bombing on a number of later economic development measures at both the district and provincial levels. In the empirical analysis we find no robust adverse impacts of U.S. bombing on poverty rates, consumption levels, electricity infrastructure, literacy, or population density through 2002, and these results are consistent across a variety of specifications and samples. There is a moderate negative effect of U.S. bombing on consumption levels through 1992/1993 but also faster consumption growth between 1992/1993 and 2002, suggesting that any negative short-run war impacts on local living standards dissipated over time as a result of rapid catch-up growth. While we unfortunately cannot fully characterize the precise mechanisms underlying these main results, and in particular there is no reliable data on labor mobility across Vietnamese districts during the immediate postwar period, there is evidence that extra state investment in heavily bombed regions during the early 1980s played a role in the postwar recovery, which is consistent with the theoretical predictions of the model. These patterns provide highly suggestive evidence against poverty trap models of economic growth.⁴ If the destruction wrought by the most severe bombing in human history, in one of the world's poorest countries, was insufficient to push Vietnam into a persistent poverty trap, it is hard to imagine where else a conflict-induced poverty trap might prevail.

The key issue for inference is the non-random nature of U.S. bombing patterns. If regions with unobservably better economic growth prospects were more (or less) likely to be heavily bombed, this could bias estimated impacts. Understanding the sources of variation in U.S. bombing is thus critical. An innovation of this paper is our attempt to address the endogeneity of bombing. In this regard, the estimation strategy benefits from the fact that the most heavily bombed areas were located near the 17th parallel north latitude, the border between North and South Vietnam during the war. This arbitrary border, set by the 1954 Geneva Accords that ended French colonialism in Indochina, became a locus for heavy fighting during the war, and its placement at 17°, rather than 16° or 18°, can be viewed as a natural experiment. The border was not drawn by Vietnamese, but was instead the outcome of fierce negotiations among the United States and Soviet Union in the context of the Cold War. The U.S. sought to push the border farther north, the Soviet Union south. We use the north–south distance from a district to the 17th parallel as an instrumental variable for bombing intensity in our preferred specification, exploiting this source of variation.⁵

⁴ Other have questioned the empirical plausibility of poverty trap models, notably [Srinivasan \(1994\)](#), who argues strongly against nutrition-based efficiency wage models, but we are among the first to assess the empirical relevance of economy-wide conflict-induced poverty traps, like those discussed in [World Bank \(2003\)](#) and [Sachs \(2005\)](#).

⁵ The second main concentration of heavy U.S. bombing lies in areas where the Ho Chi Minh Trail entered South Vietnam. While not as clearly exogenous as the North–South Vietnam border, the outlets of the Ho Chi Minh Trail into South Vietnam reflected, to a large extent, geographical conditions along the South Vietnam–Cambodia border rather than local socioeconomic conditions within Vietnam. At its main southern outlet, there was less mountainous terrain than is the case farther north along the border, facilitating troop movements into the Mekong Delta flatlands.

One limitation is that while this econometric strategy provides estimates of differences across districts, the approach is unable to capture aggregate nation-wide effects of the war on Vietnamese development. The counterfactual – Vietnamese economic performance in the absence of the “American War” – cannot be observed or estimated. This is potentially important to the extent that the war led to major institutional and social changes, or if the cross-region spillovers of the war within Vietnam were large. Still the rapid rate of economic growth in Vietnam since the early 1990s – at 6% on average between 1993 and 2003 ([World Bank, 2004](#)) – indicates that any nation-wide war impacts on economic growth rates were not persistently negative, and did not generate a national-level poverty trap. Note that the within-country empirical approach adopted in this paper also has merits. Exploiting the common data sources and postwar institutions and policies across Vietnamese regions allows us to pinpoint local economic impacts of bombing more precisely than is possible in cross-country analyses, where controlling for national trends and institutions is more problematic.

In related work, [Davis and Weinstein \(2002\)](#) show that the U.S. bombing of Japanese cities in World War II had no long-run impact on the population of those cities relative to prewar levels, and [Brakman et al. \(2004\)](#) find a similar result for postwar Germany.⁶ [Organski and Kugler \(1977, 1980\)](#) find that the economic effects of the two world wars tended to dissipate after only 15–20 years (similar to our postwar timeframe of roughly 25 years), for both capitalist and socialist economies, after which there was a return to prewar growth trends. [Przeworski et al. \(2000\)](#) similarly find rapid postwar recovery in a cross-country analysis.

We view our results as complementary to these earlier studies. We are able to measure the long-run impact of bombing on a larger set of outcomes than other studies, which either only focus on population effects or on aggregate growth. By examining the effect of bombing on (i) variables that are central to leading economic growth theoretical models – physical capital, human capital and population – and on (ii) variables that relate directly to human welfare, including poverty rates and consumption, we believe that we paint a broader picture of long-run bombing impacts.

In terms of other differences with existing studies, note that Vietnam during the 1960s and 1970s was much poorer than either Japan or Germany and was an overwhelmingly rural country. The urban agglomeration effects emphasized by some theories thus likely played a less important role in Vietnamese recovery, while poverty trap models are more relevant. Another major difference between postwar Vietnam and Japan is that the former was a centrally planned economy until it launched market reforms in the late 1980s while the latter was always a market economy. This raises the question of what general lessons we can learn from these empirical studies, since other countries with different institutions might have reacted differently. It is important to emphasize that institutions are often quite country specific: Japan has unique capitalist institutions that differ from the U.S., for example, and the Vietnamese form of socialism was quite different from East German central planning. In our view it is only through the accumulation of evidence across many settings that researchers can create a convincing picture of war's long-run economic effects.

To be absolutely clear, the humanitarian costs of the Vietnam War itself – which led to millions of civilian deaths by all accounts – were massive and the short term disruptive economic effects were certainly quite strong. No matter how rapid the recovery, the war, in addition to all the direct pain and suffering it wrought, meant an enormous amount of time and energy was wasted fighting rather than engaging

⁶ In subsequent work, scholars have found some evidence of multiple equilibria in city population growth after intense WWII bombing in Germany, see [Bosker et al. \(2007\)](#).

in economically productive activities. Vietnam's southeast Asian neighbors did not suffer from the American War, and income per capita was \$16,481 in Malaysia and \$8666 in Thailand but only \$3256 in Vietnam in 2005 (in 2005 U.S. dollars at PPP).⁷ This gap provides suggestive evidence that Vietnam, despite its high recent growth rates, might be much richer today had it not been for the war, although this is admittedly speculative given all of the other institutional, social and policy differences between these countries.

2. Theoretical framework

This section explores the possible long-run effects of wartime bombing from the point of view of economic theory. In the neoclassical growth model, war should have only temporary effects. However, long-run effects may prevail if there are poverty traps. We then discuss the conditions and policies under which local poverty traps would exist or might be eliminated.

2.1. Economic theory and the effects of war and economic growth

It is useful to first recall results from the standard neoclassical economic growth model to provide a baseline perspective on war's possible economic impacts. If war leads to the partial destruction of the physical capital stock but the production function remains unchanged, there will be a temporary increase in capital accumulation until the steady state is again attained. In other words, war has no long-run effects on the economy but leads to a transitory increase in investment and consumption growth relative to a situation without war. If war leads to a loss of the capital stock in some areas but not others, the former will experience temporarily higher growth. If capital is mobile, capital will also flow to the war-damaged areas so as to equalize marginal returns across regions. Postwar recovery patterns are qualitatively similar for human capital (see Barro and Sala-i-Martin, 2003 for a fuller treatment of two-sector growth models). A reduction in human capital in a war-torn region will also result in more rapid postwar accumulation of human capital there, though again there will be no change in the steady state provided that other model parameters are unchanged.⁸

The steady state of the economy could be affected by war, however, if it falls into a poverty trap (Azariadis and Drazen, 1990; World Bank, 2003). Given its very low initial income and the extensive bombing, if ever a war induced "poverty trap" would be possible Vietnam would be a good candidate.

Beyond the loss of physical and human capital, war could also lead to institutional changes that would affect the aggregate production function, by modifying its scale parameter. Theory does not provide an unambiguous prediction as to the effect of war on institutions and technology. Deterioration in institutions could lead to a new steady state characterized by a lower long-run level of both capital and income, while by symmetry, positive institutional changes brought about by war could boost steady-state capital and income postwar.

⁷ Source: Penn World Tables. These patterns are discussed further in Fisman and Miguel (2008). We cannot rule out other explanations for the higher income levels in Malaysia and Thailand compared to Vietnam such as for example better economic policies and institutions in those countries.

⁸ The effects of a loss of capital stock in a vintage capital model are different. If postwar investment consists of more recent and better quality capital, economic performance could eventually exceed that of the prewar economy and thus regions that suffered more from the war might eventually overtake regions that suffered less. Gilchrist and Williams (2004) indeed argue that a vintage capital growth model is more consistent with macroeconomic recovery patterns in postwar Japan and Germany than the standard neoclassical model. Our main empirical findings below appear to be consistent with both the neoclassical and vintage capital views, and we do not attempt to decisively distinguish between these two models below since for us the key issue is to determine whether or not persistent adverse economic impacts can be detected, as a way to assess the empirical validity of poverty trap models.

The possibility of cross-regional spillovers is also important to the extent that economic conditions in one region affect growth elsewhere. Central government taxation and transfers may also benefit some regions more than others, an issue we develop in the formal model in the next sub-section. In the empirical analysis below, we also explore the possibility of cross-district spillovers by examining relationships at different levels of aggregation (namely, at both provincial and district levels), and also examine postwar state investment patterns to establish whether the areas most affected by U.S. bombing benefited from additional investment.

2.2. A simple theoretical framework of regional war destruction

We focus our theoretical discussion on two plausible alternatives: the standard neoclassical growth model and a model including poverty traps. We first introduce a version of the standard Solow model based on districts within a country. Assume a country has $i = 1, \dots, n$ districts. District i is assumed to have a Cobb–Douglas constant returns to scale production function, $Y_{it} = AK_{it}^\alpha L_{it}^{1-\alpha}$ where Y_{it} is district output and K_{it} and L_{it} are, respectively, the stock of capital and the labor force in district i . (We ignore human capital here for simplicity but many of the implications for physical capital also hold for human capital, as discussed above.) Assuming a constant saving rate s for simplicity, such that $S_t = sY_t$, and assuming a per period capital depreciation rate δ , annual investment is equal to $I_t = \Delta K_{t+1} + \delta K_t$. Equating savings with investment leads to the dynamics of capital accumulation:

$$K_{i,t+1} = (1 - \delta)K_{it} + sY_{it}. \quad (1)$$

Expressing quantities in per capita terms, capital intensity is $k_{it} = K_{it}/L_{it}$, and the production function is $y_{it} = Ak_{it}^\alpha$ with $y_{it} = Y_{it}/L_{it}$. Dividing the capital accumulation equation by L_{it} :

$$(1 + n)k_{i,t+1} = (1 - \delta)k_{it} + sy_{it} \quad (2)$$

where n is the population growth rate.

In a modification of the standard model, assume there is a minimum subsistence consumption level $c_{min} > 0$ below which consumption per capita cannot fall. In that case, per capita savings in district i are given by $s_{it} = \min\{y_{it} - c_{min}, sy_{it}\}$. If the per capita consumption hits the c_{min} constraint, a poverty trap will result: there is a capital intensity level below which there will be no further per capita capital accumulation: $k_{i,t+1} \leq k_{it}$. Indeed, multiplying both sides of this inequality by $(1 + n)$ and using $(1 + n)k_{i,t+1} = (1 - \delta)k_{it} + (y_{it} - c_{min})$ when the subsistence consumption constraint is binding, we find that $k_{i,t+1} \leq k_{it}$ if and only if:

$$Ak_{it}^\alpha \leq (n + \delta)k_{it} + c_{min}. \quad (3)$$

Given this inequality, there is a $k_{trap} > 0$ below which inequality (3) is strictly satisfied, and this k_{trap} is the poverty trap threshold level of capital intensity. It is straightforward to see that k_{trap} increases with c_{min} , n and δ , thus a higher minimum consumption level, faster population growth, and a higher depreciation rate all increase the poverty trap level of k_{trap} .

To derive the steady state in the context of multiple districts, we need to make assumptions on both the nature of factor mobility and government policy. Assume first that there is no factor (capital or population) mobility across districts, and that initially at time zero $k_{i,0} > k_{trap}$ in all districts. We assume that both $k_{i,0}$ and k_{trap} are far below the steady-state level of capital accumulation per capita, k^* (defined such that $(1 + n)k^* = (1 - \delta)k^* + sAk^{*\alpha}$), an assumption made to ensure that there is transitional economic growth.

Now imagine that at a later time t , however, $m < n$ districts are hit by a bombing shock destroying much of the local capital stock and

bringing k_{it} below k_{trap} in these districts.⁹ In the absence of factor mobility or government redistribution, those m districts will fall into a poverty trap, permanently condemning them to low income, while the remaining $n - m$ districts (where capital intensity is above the critical k_{trap} level) will continue to experience positive economic growth. In this case, bombing would lead to persistent differences in per capita income (as well as in physical capital intensity) between bombed and non-bombed districts.¹⁰

There are at least two sets of policies or conditions that would alter this conclusion on the likelihood a poverty trap would prevail. Assume first that there is extensive factor mobility across districts within the same country. With mobile labor, then for any two districts i and j , after the bombing there should be a reallocation of labor such that the marginal products of labor are equalized across districts: $F_{iL} = F_{jL} \Leftrightarrow (1 - \alpha)Ak_{it}^\alpha = (1 - \alpha)Ak_{jt}^\alpha \Leftrightarrow k_{it} = k_{jt}$. Similarly, if capital is mobile, marginal products of capital should be equalized across districts. There should thus be equal capital intensity k^M and per capita income across districts once sufficient time has passed for labor and capital to be optimally reallocated.¹¹

Depending on whether k^M is above or below k_{trap} , there will be either the same positive growth rate in all districts or zero growth in all districts, as all have entered into a poverty trap¹². With perfect factor mobility, there will thus be no long-run divergence in income between the districts that are bombed heavily versus the other districts. There may be a long-run nation-wide effect of bombing if it pushes the entire country into a poverty trap, but this occurs in all districts.

Next assume that the government has sufficient authority to intervene in the economy and reallocate capital across districts. Consider the case where all districts start out below the poverty trap level of capital accumulation k_{trap} . Private agents are unable to internalize the growth externality inherent in a poverty trap, but simply reallocate factors of production to those districts that have the highest marginal return (in this case, zero). Yet as long as there is sufficient capital in the economy as a whole for the government to redistribute to a single district i' and bring capital intensity there above the poverty trap level, $k_{i't} > k_{trap}$, then the government can allow capital to accumulate in that district until a time t' when “excess” capital there $L_{i't}(k_{i't} - k_{trap})$ can be redistributed to a second district to bring it above the poverty trap level of capital intensity. That second district will thus leave the poverty trap and start accumulating capital on its own as it transitions to a higher steady-state income level. Capital accumulated above k_{trap} in these growing districts can then gradually be injected into all other poor districts until the entire country has exited out of the poverty trap.

To summarize the theoretical discussion, wartime bombing can generate long-run income divergence between regions that were heavily bombed versus those that were not if poverty traps are possible, namely if capital accumulation is brought to a halt when per capita consumption falls below a minimum threshold in the bombed regions. However, even if the poverty trap consumption threshold

exists, we would not observe inter-regional economic divergence if factors (labor and capital) are mobile, as in that case either all regions or none would fall into the poverty trap. Moreover, even a national-level poverty trap can be prevented if the government has the authority to reallocate resources across regions, lifting the more heavily affected regions out of the trap.

There are some limits to how closely we can tie this framework to the available data for Vietnam to directly test the above predictions. There is unfortunately no reliable Vietnamese per capita consumption data at the sub-national level, nor data on inter-regional labor mobility, for the 1970s and 1980s, the immediate post-bombing period. We can, however, examine government investment patterns at the province level in the immediate postwar period, and can test the model's reduced form implications by examining the effects of wartime bombing on district poverty and consumption levels and growth, as well as other economic development measures, since the early 1990s.

3. Data and econometric methods

3.1. Data description

We use a database assembled by the Defense Security Cooperation Agency (DSCA) housed at the United States National Archives in Record Group 218, called “Records of the U.S. Joint Chiefs of Staff”.¹³ The database contains information on all ordnance dropped from U.S. and allied airplanes and helicopters in Vietnam between 1965 and 1975, as well as artillery fired from naval ships.¹⁴ To our knowledge, these files embody the most complete, comprehensive and reliable summary available of U.S. and allied ordnance expended during the Vietnam War. Some of the original tape archives were reportedly damaged so up to several months of data may be missing, but unfortunately we are unable to determine the precise extent of any missing data. The data were originally recorded in aircraft mission logs and then reported to Pacific Command and the Joint Chiefs of Staff. They were declassified and provided to the Vietnamese government following the war.

The raw data include the bombing location, a summary bomb damage assessment (which we unfortunately do not have access to), and the quantity of ordnance by category and type. Categories include general purpose bombs, cluster bombs, chemicals, incendiary, rockets, missiles, projectiles, ammunition, mines and flares. Ordnance is measured in units rather than by weight. Since the source of the data is the U.S. Air Force and Navy, we miss anti-personnel landmines that were placed by Army ground forces, which probably accounts for a large share of U.S. landmines, and the landmine data are thus less reliable than the other data. The raw data were then geo-coded by the VVAF using Vietnam district boundaries employed in the 1999 Population and Housing Census to yield the dataset we use. (An example of the raw data is presented in [Appendix Fig. 1](#).)

General purpose bombs are by far the most common ordnance category ([Table 1](#)). The Mark 82 and Mark 36 Destructor general purpose bombs typically weighed between 500 to 750 lbs. Bombing intensity was high, with an average of 32.3 bombs, missiles, and rockets per km² nationwide through the war, and there is extensive variation across districts for all ordnance categories. The distribution of bombing was skewed, with 10% of districts receiving nearly 70% of all bombs, missiles and rockets¹⁵, and some districts receiving over

⁹ The bombing shock may also reduce local population, but because people can hide or flee from bombing, we assume that the destruction of capital stock is proportionally larger than for the labor force, such that bombing leads to a reduction in physical capital intensity k .

¹⁰ Note here that we do not consider the case in which the local scale parameter A_i , capturing local institutions and technology, is directly impacted by the bombing. We do not believe that cross-district variation institutional quality is sufficiently large in Vietnam to justify this approach, especially in the context of the strongly centralized policy environment that characterized postwar Vietnam. However, note that persistent differences in local institutions due to bombing damage would be another way to generate lasting income gaps across regions.

¹¹ The poverty trap prevents savings in a district if income falls below a certain level. However, the marginal return of capital is not affected by the “trap” and thus capital equalization still occurs under factor mobility.

¹² Individual investors do not internalize the effects of their individual investment decisions on capital accumulation in their district. When there is no investment in the whole economy, it is implicit (though not explicitly modeled) that wealthier individuals lend to poorer individuals to finance the minimum consumption level.

¹³ We obtained the data from the Vietnam Veterans of America Foundation (VVAF) with authorization from DSCA and the Vietnam Ministry of Defense Technology Center for Bomb and Mine Disposal. The Data Appendix discusses data sources in greater detail.

¹⁴ In particular, data come from the 1965–70 Combat Activities-Air (CACTA), the 1970–1975 South East Asia (SEADAB), and Combat Naval Gunfire (CONGA) databases. Unfortunately, it is simply the total over the time period and is not disaggregated by year.

¹⁵ Quang Tri district in Quang Tri province, which is only 6 km² in size, received over 3000 bombs per km², the highest by far. We exclude this outlier in the analysis while still using data from the rest of Quang Tri province.

Table 1
Summary statistics – U.S. ordnance data, 1965–75.

	Mean	S.D.	Max.	Obs.	Correlation with general purpose bombs
<i>Panel A: district-level data</i>					
Total U.S. bombs, missiles, and rockets per km ²	32.3	68.5	561.5	584

<i>Panel B: province level data</i>					
Total U.S. bombs, missiles, and rockets per km ²	30.6	51.7	335.5	55	

Notes: The summary statistics are not weighted by population. The minimum value is zero for all variables at the district level, and thus we do not present this in the table. The sample throughout excludes Quang Tri district (one district within Quang Tri province), which has by far the highest total U.S. bombs, missiles, and rockets intensity per km², at 3148; this outlier is excluded from the analysis throughout. Significant at 90(*), 95(**), and 99(***). percent confidence.

500 bombs per km², while many districts were not bombed at all. The most intense attacks took place near the 17th parallel that formed the border between North and South Vietnam during the war. Note that the poor northwestern region was hardly bombed at all, in part because of the Johnson administration's reluctance to antagonize China by bombing near its borders (Tilford, 1991: 153).

There is a positive and statistically significant correlation across all ordnance categories (Table 1). In the analysis below, we mostly employ total intensity of bombs, missiles, and rockets per km², but given the substantial correlation with other ordnance categories (e.g. ammunition), this is also a good proxy for overall war activity. Unfortunately, we do not have comparable data for North Vietnam Army or NLF/Vietcong ordnance nor do we have ordnance damage measures. Although we do not have disaggregated Agent Orange exposure data, the broad regional patterns of exposure from the maps in Stelman et al. (2003) correspond closely with those in our data base.

We obtained 1960–61 provincial population density from both South Vietnam and North Vietnam government sources (see the Data

Appendix) and use those data as baseline controls in the regressions (Table 2). A variety of district geographic and climatic characteristics – including proportion of land at high altitude, average district temperature and precipitation, location in former South Vietnam, and the proportion of land in 18 different soil type categories – are also included as explanatory variables to partially control for agricultural productivity (an important component of the scale factor *A* in the economic growth framework for an agrarian society) and factors potentially affecting military strategy (e.g., altitude). The soil controls are excluded from the province level analysis due to limited degrees of freedom, as there are only 55 provinces in the province sample. The analysis principally focused on the more disaggregated district level (*N* = 584) but some analysis is conducted at the more aggregated province level (*N* = 55) for a robustness check, and in particular to capture cross-district externalities.

We focus on multiple economic outcomes that flow from the economic growth framework discussed above, and others that are of independent policy interest. Poverty rate estimates are from Minot et al. (2003), who use the Elbers et al. (2003) local regression method.

Latitude – 17°N	5.0	2.0	0.3	8.1	55

Notes: The summary statistics are not weighted by population. District latitude is assessed at the district centroid, and province latitude is the average of the district latitudes, weighted by district land area.

This approach matches up 1999 Population and Housing Census data – which has excellent geographic coverage but limited household characteristics – with detailed 1997/8 Vietnam Living Standards Survey (VLSS) household data. Log-linear regressions of real cost-of-living-adjusted per capita consumption expenditures on the 17 household characteristics found in both the census and VLSS are then carried out, and the results used to compute predicted household consumption (details are in the [Data Appendix](#)). The poverty rate is the proportion of population estimated to be living on less than the official 1999 national poverty line of 1,789,871 Dong, and approximately 41% of the national population met this criterion ([Table 2](#)). Related methods generate predicted average consumption levels and the Gini coefficient (in per capita consumption) at the district level. The 1999 census also provides information on household access to electricity (71% of households nationwide) and literacy (88% of respondents), our proxies for past physical and human capital investments, respectively.

We obtained actual per capita consumption expenditure data from both the 1992/3 and 2002 VLSS waves for a sample of households in a subset of 166 districts. We focus on province level averages with the VLSS, since the data was designed to be representative at this level of aggregation. The disadvantage of this data set is its relatively small sample size of households. The VLSS also contains useful retrospective information on migration that we discuss below.

Finally, Vietnamese Statistical Yearbooks provide a consistent series on province population for 1985 to 2000, and some information on central government investment flows for 1985. Unfortunately, more detailed sub-national economic data is lacking for the 1970s and 1980s, a period which constitutes a sort of statistical black hole. Recall that in the aftermath of the “American War”, Vietnam also fought a border war with China and occupied Cambodia to end Khmer Rouge rule, and data collection was a low priority for the regime while the country remained on a war footing.

Based on national accounts data in the Penn World Tables, average living standards were extremely low in Vietnam immediately after the war ended in 1975. Per capita income (in 2005 U.S. dollars at PPP) was only \$964 in 1976, which was nearly identical to levels in Burkina Faso and below Niger and Sierra Leone in that year, placing Vietnam among the world's fifteen poorest countries in per capita terms. Numerous academic and Vietnamese government sources all confirm that the late 1970s were a period of mass deprivation, food shortages, and pervasive poverty, as the country dealt with the legacy of wartime destruction as well as sharp reductions in foreign aid ([Dinh, 2003](#); [Harvie and Hoa, 1997](#); [Kim 1992](#)). We conclude that it is reasonable to test for the presence of a poverty trap in this extreme setting.

3.2. Econometric approach

We focus on the following cross-sectional regression, where the unit of observation is typically the district, denoted with subscript i :

$$y_{it} = \alpha + X_i'\beta + \gamma BOMBS_{i, 1965-75} + \varepsilon_{it}. \quad (4)$$

The dependent variables, y , are different outcomes important in economic growth models, including per capita consumption levels and growth (and related living standards variables, the poverty rate and degree of inequality), population density, and both physical and human capital investment levels. While some variables are generated using local area regression methods, their use as dependent variables does not typically require additional regression adjustment (see [Elbers et al., 2005](#)).

The vector X contains fixed district characteristics including geographic controls (soil type, elevation, and latitude) and population density in 1960 (the pre-U.S. bombing baseline period), that are meant to partially proxy for differences in steady-state outcomes. The $BOMBS$ term is the total intensity of bombs, missiles, and rockets

dropped in the district during 1965–1975 per km². The coefficient estimate on $BOMBS$ is the main parameter of interest, capturing the difference in outcomes in the postwar period between areas more versus less affected by the U.S. bombing, which we relate to the theoretical predictions of the poverty trap model described in [Section 2.2](#). We explored different measures of intensity, including indicators for the most extreme bombing levels, and as we discuss below, these yield similar results. The disturbance terms, ε_{it} , are normally distributed and allowed to be correlated (“clustered”) across districts within the same province, although the results are nearly unchanged when they are allowed to be spatially autocorrelated using the [Conley \(1999\)](#) method.

Below, we consider bombing impacts at both the province and district levels. There are a number of reasons to consider outcomes at different levels of aggregation. First, U.S. bombing of one district could generate negative externalities for nearby districts. Provincial level regressions are one way to partially capture these externalities, although they still miss even broader national effects. Second, the main baseline 1960–61 population density control is at the province level, and thus when population density is the dependent variable at least (in [Section 4.3](#) below), a lagged dependent variable can be included as a control.

3.3. Determinants of U.S. bombing intensity and the instrumental variable approach

Before presenting the results, we discuss the existing literature on U.S. bombing strategy during the Vietnam War. A distinction is often made between the nature of bombing in North Vietnam and in South Vietnam. U.S. bombing in North Vietnam is largely considered *strategic bombing*, targeting transportation capabilities (e.g., airfields, railroads, bridges, ports, roads), as well as military barracks, industrial plants, and storage depots ([Clodfelter, 1995](#): 134). The selection of targets in North Vietnam was directly supervised by Washington officials on a weekly basis during the Johnson administration's “Rolling Thunder” air campaign ([Littauer and Uphoff, 1972](#): 37), and the number of approved targets regularly fell below the requests of the military, with the bombing of Hanoi, Haiphong and areas near China categorically ruled out. A broader set of targets was approved under the Nixon administration's “Linebacker” campaign, including the major population centers.

Bombing in South Vietnam, and in parts of North Vietnam near the border, in contrast, was typically *interdiction bombing* or tactical air support, which aimed to disrupt enemy troop movements and support U.S. ground troop operations, rather than explicitly to destroy infrastructure ([Littauer and Uphoff, 1972](#): 55; [Schlicht, 1988](#): 292). Below we present empirical results broken down by the former North and South Vietnam in some cases, in addition to full sample estimates, to investigate differential impacts. Some existing research suggests there was no robust correlation between local population density and U.S. bombing intensity ([Nalty, 2000](#): 83) but other authors claim poorer areas were actually more likely to be hit: “[i]n the remoter, sparsely populated regions often used by the NLF/NVA [North Vietnam Army] for staging, regroupment, and infiltration, area saturation bombing is common” ([Littauer and Uphoff, 1972](#): 10–11).

The central estimation concern is the non-random geographic placement of U.S. bombing, in response to military strategy and needs, and most worryingly, potentially in response to local economic conditions. To address these concerns we develop an instrumental variable approach that relies on the arbitrary placement of the North Vietnam–South Vietnam border at the 17th parallel north latitude, as a result of Cold War negotiations between U.S. and Soviet officials. The first stage relationship relates bombing intensity to the district's distance from the border ($DISTANCE$):

$$BOMBS_{i, 1965-75} = a + X_i'b + cDISTANCE_i + e_{it}. \quad (5)$$

The north–south distance from the 17th parallel is a strong predictor of bombing intensity and is statistically significant in the province level analysis (Table 3, regression 1), district-level analysis (regression 2), and a specification that excludes Quang Tri province, the most heavily bombed province (regression 3), as a robustness check. The main district-level specification in regression 2 serves as the first stage for the subsequent IV-2SLS analysis. Note that the instrument is highly statistically significant with a t-statistic near three in that case.

A remaining econometric concern is whether the instrumental variable violates the exclusion restriction, in the sense that distance from the 17th parallel has an independent impact on postwar outcomes beyond any effects working through bombing intensity (conditional on the control variables). One possible concern is that the IV is correlated with distance to one of Vietnam's two major cities, Hanoi and Ho Chi Minh City. If remoteness from these two booming metropolitan areas is associated with lower incomes during the postwar period, as seems likely, this would generate a negative correlation between distance to the 17th parallel and poverty in 1999. However, despite any such possible bias, below we find no significant relationship between bombing and later poverty in the IV specification. In other words, despite the fact that districts near the 17th parallel had the double misfortune of being both heavily bombed and far from major national markets, they are currently no poorer than other regions (conditional on baseline characteristics).

None of the other explanatory variables is significantly related to U.S. bombing intensity in a consistent way across the three specifications in Table 3, including the indicator for former South Vietnam, altitude measures, climatic conditions and latitude. The one partial exception is the prewar 1960–61 province population density measure, which is negative and statistically significant across the two district-level specifications, suggesting that more rural areas were somewhat more likely to be bombed, echoing some of the existing historical literature. However, note that this result does not hold in the province level analysis in regression 1. Thus overall, with the

exception of distance to the 17th parallel (the instrumental variable), there are no consistent correlations between observables and bombing intensity, partially alleviating the leading omitted variable bias concerns.

4. The long-run impact of bombing Vietnam

4.1. Impacts on poverty and consumption expenditures

Total U.S. bombing intensity is negatively and marginally statistically significantly related to the 1999 poverty rate at both the province level (Table 4, regression 1) and the district level (regression 2) in OLS regressions. The district-level relationship between bombing intensity and poverty is presented graphically in Fig. 2. The main empirical results are similar if we consider only the intensity of general purpose bombs, the major ordnance category, or if we consider a log transformation of total bombing intensity (not shown). In terms of other factors, areas that had higher population density in 1960–61 have significantly less poverty in 1999 as expected, as does South Vietnam as a whole on average, while high altitude areas have considerably more poverty (regressions 1 and 2). Climatic factors and latitude, in contrast, are not robustly associated with poverty, although high precipitation areas have significantly more poverty in some specifications.

The district-level effect remains negative and is even more statistically significant in specifications that include province fixed effects (Table 4, regression 3) and exclude Quang Tri (regression 4). Overall, the OLS specifications provide suggestive evidence that U.S. bombing if anything moderately reduced later poverty, but estimates are only marginally significant and not particularly robust. This negative relationship may in part reflect the fact that some of the poorest provinces in Vietnam, those in the northwest, were rarely bombed by the U.S. due to their proximity to China, generating a spurious correlation. More generally, some other unobserved source of socioeconomic variation or potential could be driving both bombing patterns and later poverty.

We thus next turn to estimates that rely on the placement of the North Vietnam–South Vietnam border at the 17th parallel as exogenous variation in bombing intensity. In the reduced form specification (Table 4, regression 5), the north–south distance from the 17th parallel is negative but not statistically significantly related to 1999 poverty, conditional on all other geographic factors. Using this distance as an instrumental variable for bombing intensity in our preferred specification, the relationship between bombing intensity is positive but not statistically significant (regression 6): the coefficient estimate on total bombing intensity is 0.00026 (standard error 0.00042).

To get an idea of the magnitude of this estimated bombing impact on later poverty, first consider the effect of a change from zero bombing up to the average bombing intensity of 32.3 bombs, missiles, and rockets per km². The average effect in this sense is $(32.3) \times (0.00026) = 0.008$. This is a very small average effect, an increase in the poverty rate by less than one percentage point and it is not statistically significant. In terms of how precise this estimate is, the 95% confidence interval ranges from $0.00026 - 2 \times 0.00042 = -0.00058$, up to $0.00026 + 2 \times 0.00042 = 0.0011$. Thus again considering the effect of going from zero bombing up to the average intensity of 32.3, the 95% confidence band of estimates is $(32.3) \times (-0.00058) = -0.019$ to $(32.3) \times (0.0011) = 0.035$. In other words, plausible average effects range from a 1.9 percentage point reduction in poverty up to a 3.5 percentage point increase in poverty on a base poverty rate of 41%, a reasonably tight range. The analogous exercise using the OLS estimate (Table 4, regression 2) yields a point estimate of $(32.2) \times (-0.00040) = -0.013$, a 1.3 percentage point reduction in poverty (going from zero bombing up to average bombing intensity), and a 95% confidence interval from a –2.7 percentage point decrease

The instrumental variable in regression 6 is |Latitude − 17°N|.

in poverty up to a +0.1 percentage point increase, again a narrow range of estimates around zero.

The effect of bombing on poverty is negative and statistically significant in former North Vietnam (Table 5, regression 1) but not in former South Vietnam (regression 2). The explanation for this North–South difference is not entirely clear but it might reflect a postwar government bias towards assisting heavily bombed areas in the North, or the different nature of bombing across the two regions. Bombing effects are not statistically significant in initially rural areas (districts with baseline 1960–1 population density less than 200 per km², regression 3) but are statistically significant and negative in urban areas

(regression 4). There is some evidence for a nonlinear effect of bombing intensity on later poverty rates: the linear bombing term remains negative and statistically significant while the squared term is positive and significant (regression 5). This pattern appears to in part reflect the high poverty rates in Quang Tri province, the most heavily bombed province in the country and suggests that war impacts might persist for extremely intense bombing like that in Quang Tri, although that claim is speculative. Point estimates are however not statistically significant using an alternative nonlinear measure of heavy bombing (regression 6). In additional results not shown in the tables, we find that alternative district-level welfare measures – the imputed average per capita consumption level, and the Gini coefficient in consumption – are not significantly related to U.S. bombing intensity at traditional levels.

Using the more detailed (but more aggregated) VLSS household consumption expenditure data, average consumption per capita in 2002 is not robustly associated with bombing intensity across the full sample (Table 6, Panel A, regression 1), or in a specification that excludes Quang Tri province (regression 2), or in a specification that includes the north–south distance to the 17th parallel as the main explanatory variable (regression 3). In contrast, all three specifications indicate that more heavily bombed provinces were somewhat poorer in 1992/93 (Table 6, Panel B), although effects are not significant at traditional confidence levels. We find that provinces that experienced more intense U.S. bombing had significantly faster per capita consumption growth between 1992/93 and 2002 (Table 6, Panel C), and this effect is significant at 95% confidence. The coefficient estimate from the full sample (regression 1) implies that going from zero to average U.S. bombing intensity is associated with (32.3) (0.0030) or 10 percentage points faster consumption expenditure growth during that ten year period, a substantial difference that works out to be roughly one percentage point faster growth per year on average.

These patterns suggest that more heavily bombed areas were somewhat poorer than other areas soon after the war but they later

Fig. 2. 1999 estimated district poverty rate vs. total U.S. bombs, missiles, and rockets per km² in the district (conditional on 1960–61 province population density, South Vietnam indicator, district average temperature, average precipitation, elevation, soil controls, and latitude).

Notes: Ordinary least squares (OLS) regressions. Robust Huber–White standard errors in parentheses. Significant at 90(*), 95(**), and 99(***) percent confidence. Disturbance terms are clustered at the province level. District demographic and geographic controls include Population density (province) 1960–61, Former South Vietnam, Proportion of land area 250–500 m, Proportion of land area 500–1000 m, Proportion of land area over 1000 m, Average precipitation (cm), Average temperature (Celsius), and Latitude (°N). The district soil type controls include the proportion of district land in 18 different soil categories. The omitted altitude category is 0–250 m.

caught up during the 1990s economic boom, in line with the neoclassical growth model's prediction of especially rapid consumption growth along the transition path to steady state. Unfortunately, due to data limitations we cannot trace out consumption growth patterns in the 1970s and 1980s, and so cannot estimate the extent of poverty immediately postwar. Nevertheless, by 2002, nearly thirty years after U.S. troops pulled out of Vietnam, living standards in the provinces that bore the brunt of the U.S. assault are largely indistinguishable from other areas.¹⁶ This is strong evidence against persistent local poverty traps: in that framework, consumption growth rates would be significantly faster in areas that had experienced less bombing, while the heavily bombed areas would stagnate or even experience falling per capita consumption.

4.2. Impacts on physical infrastructure and human capital

There is a positive relationship between U.S. bombing intensity and 1999 access to electricity across the standard set of province and district specifications (Table 7, Panel A), and coefficient estimates are statistically significant at 95% confidence in six of seven specifications. The relationship is weaker when province fixed effects are included as controls (regression 3), but the point estimate on U.S. bombing remains positive and marginally statistically significant even in that case. Note the negative and significant coefficient estimate on north–south distance to the 17th parallel, suggesting particularly intensive power sector investments near the former border.

Taken together these estimates provide some evidence of technological “leapfrogging” in the heavily bombed regions, consistent with either a vintage capital growth model, or investments in the heavily bombed regions that exceeded war damage. Speculatively, this may have been a political reward for regions that actively resisted the U.S. during the war. However, given the limited data available immediately postwar, we have little hope of determining the relative

contributions of these two explanations. Infrastructure investment decisions in Vietnam in the 1970s, 1980s and 1990s likely reflected a combination of central government redistributive goals as well as potential private returns, especially in the aftermath of the economic reforms, and it is difficult to disentangle these motives in the absence of detailed micro-level public and private investment data, which do not exist to our knowledge. International donors, non-governmental organizations (NGOs) and even the U.S. government (following the 1995 normalization of relations with Vietnam) also played important roles in reconstruction, further complicating interpretation.

Another key factor in economic growth models is human capital. There are no statistically significant negative impacts of bombing on either province or district literacy rates in 1999, a proxy for human capital investment (Table 7, Panel B, regressions 1–6), and similarly weak results hold for other 1990s human capital measures from the VLSS database as well as for 1985 school enrollment data from government yearbooks (results not shown).

There is thus no evidence that more heavily bombed districts have either less physical infrastructure or human capital stocks 25 years after the end of the war, consistent with the rapid postwar recovery in consumption levels documented above. But this is not to say that the war left no observable legacies in heavily bombed regions. For one thing, more heavily bombed provinces have higher membership in war veterans' associations – in a specification analogous to Table 6 regression 1, the point estimate is 0.00022, standard error 0.00011 – and there is suggestive, though not always significant, evidence that 2002 disability rates are somewhat higher (regressions not shown), perhaps in part due to war and landmine/UXO injuries.

4.3. Impacts on population density

Province population density in 1999 is not significantly related to total U.S. bombing intensity (Table 8, regression 1), with a point estimate of 0.13 and standard error 0.49. Provinces that had high population densities in 1960–61 also tend to have high density in 1999 (the point estimate on 1960–61 density is 0.89, standard error 0.19) as expected, and former South Vietnam has somewhat higher 1999 population density overall, although that effect is only marginally significant. In this province level specification, the effect of a change from zero up to average province level U.S. bombing intensity is (30.6) (0.13) = 4.0 additional people per km², a miniscule effect of less than 0.01 of a standard deviation in 1999 province population density, with a tight 95% confidence range from −26 to +34 people per km².

¹⁶ We examined attained adult height from the VLSS as a measure of living standards for cohorts born before and during the war to gauge the extent to which living standards fell in heavily bombed areas. We find that average height for the 1961–70 and 1971–80 birth cohorts is significantly lower in more heavily bombed regions. However, it is also somewhat lower for earlier cohorts (born pre-1961) in those same areas. The largest coefficient estimate on U.S. bombing intensity (for the 1961–70 cohort) is −0.0165, implying an average reduction of 0.5 cm when going from zero to average U.S. bombing intensity – not a large effect. The relatively small sample sizes in the VLSS, especially when the data are broken down by year of birth, gender, and province cells, and the possibility that children across a range of ages could experience some growth stunting, prevent us from drawing strong conclusions. The possibility of differential child and infant mortality as a result of the war could also generate selection effects that would further complicate the analysis.

estimates, which make these estimates less precise than the poverty results. The leading explanation for these large standard errors in the district-level regressions is the absence of a prewar *district* level population density control: 1960–61 province population density is only weakly correlated with 1999 district population density.

There is similarly no statistically significant effect of bombing on 1999 district population density in several other samples and specifications, including in former North Vietnam and South Vietnam, in rural areas (districts with baseline population density less than 200 per km²), when province fixed effects are included, and using alternative measures of bombing intensity (regressions not shown). The estimated effect of bombing is sometimes positive for urban areas but the result is not robust (not shown).

We next trace out effects on population density over time from 1985 to 2000 using Vietnamese Statistical Yearbook data, and find no effect of bombing intensity on population density in 1985 (Table 9, Panel A). We also find no effects on province population density growth rates from 1985 to 2000 (Panel B). So unlike for consumption, there is no evidence of “catch-up” population growth. Moreover, as was the case for 1999 population, there is no statistically significant effect of U.S. bombing on province population in any year from 1985 to 2000 (results not shown). This suggests that if there were any large postwar population movements into the more heavily bombed regions, they must have occurred prior to 1985. Unfortunately, disaggregated population figures are incomplete for the 1970s and early 1980s, preventing us from extending the analysis back to the immediate postwar period. Thus it remains possible that there were in fact short-run localized effects of the war on population that had dissipated by 1985.

It is plausible that this lack of population effects is due to large postwar inflows of migrants into heavily bombed districts, but while we cannot rule this out, nor do we find any compelling evidence that it is in fact the case. Using the 1997/8 VLSS, U.S. bombing intensity does not have a consistent effect on the proportion of individuals not born

in their current village of residence (Table 9, Panel C) although the point estimate is positive and marginally statistically significant in one specification (regression 2). The leading interpretation of the data is that most households displaced by the war simply returned to their home areas shortly after conflict had ended. Vietnamese communities developed elaborate responses to avoid injury during periods of intense U.S. bombing, including hiding for extended periods in well provisioned bomb shelters and in underground tunnels – thousands of miles of which were built during the war – while others fled temporarily before returning to rebuild (Herring, 2002: 174–176).

5. Discussion: why no long-run local economic impacts?

Why does the most intense bombing campaign in human history not lead to inter-regional economic divergence 25 years later? There are a variety of explanations, based on the theoretical framework, the empirical analysis, as well as our reading of the historical literature. First, much U.S. bombing targeted South Vietnam with the purpose of impeding the progress of enemy troops (both North Vietnam Army and NLF/Vietcong guerrillas) and took place in rural areas (Tilford, 1991: 105–6). These areas had little fixed infrastructure to destroy, and instead bombing often led to the destruction of forest and farmland, much of which could be expected to recover naturally over time. Even U.S. military planners recognized early in the war that “the agrarian nature of the [Vietnamese] economy precludes an economic collapse as a result of the bombing” (Pentagon Papers, 1972: 232).

Even if the impact of bombing on infrastructure in rural areas was not as devastating as the bombing intensity numbers suggest, one should not underestimate the ingenious strategies employed by the North Vietnamese to limit the damage to physical infrastructure that did occur, especially in urban areas. First of all, some industrial operations were dispersed across multiple sites (Kamps, 2001: 70). Second, according to Tilford (1991: 112) “[r]oads (such as they were) were quickly repaired. Bridges were bombed often but, in addition to

Table 9

being difficult to hit, were easily bypassed with dirt roads, underwater bridges, and pontoon bridges.” In North Vietnam up to half a million people worked rebuilding infrastructure destroyed by U.S. bombing (Herring, 2002: 176).

Another important factor counteracting the effects of U.S. bombing was the major Vietnamese government reconstruction effort after the war, with massive mobilization of labor and resources to rebuild damaged infrastructure and demine the countryside (World Bank, 2002). The theoretical model we developed in Section 2.2 above suggests that these sorts of government investment efforts were likely critical in preventing the descent into local bombing-induced poverty traps. Although we lack district-level investment data, government yearbooks contain information on total state investment by province during 1976–1985. For 1985 alone we are able to construct per capita state investment figures (complete province population data is only available for 1985), and we find that more heavily bombed provinces did in fact receive somewhat more investment (in millions of 1985 Dong per capita): in a specification analogous to Table 6, column 1, the point estimate on total U.S. bombing intensity is 0.0113 (s.e. 0.0071, regression not shown), and this effect is nearly significant at 90% confidence. This is a large effect: going from zero to average province level bombing intensity leads to an increase of 1.5 standard deviations in state investment.

Similarly, over the entire 1976–1985 period, the ratio of state investment flows (in per capita terms) for provinces above versus below the median in terms of U.S. bombing is greater than one. In other words, the more heavily bombed provinces received more state investment on average. As one can see in Fig. 3, this ratio starts close to one (equal investment across more and less heavily bombed regions) and increases rapidly after 1980, with the end of the border conflict with China and the complete occupation of Cambodia, suggesting that the redistribution of state investment across regions became stronger over time. The average ratio of state investment to heavily bombed versus other regions is 1.31 during 1981 to 1985, and reaches 1.50 in 1985, implying that heavily bombed regions received 50% more state investment in per capita terms that year. These patterns provide further evidence that the Vietnamese government attempted to allocate additional resources to heavily bombed regions,

either as a political reward or for the higher investment returns (or both). This may explain some of the gains in electricity infrastructure and may also have laid the foundation for the rapid catch-up growth in consumption discussed above.

Labor mobility may have also played a role. However, there exist no reliable figures on migration across provinces (or districts) from government and non-government data sources for Vietnam in the 1970s and 1980s. Yet there were several government-led large-scale land reform and settlement campaigns in the Vietnam in the 1980s (as discussed in UNDP, 1998). It is thus plausible that labor mobility helps explain part of the economic convergence across regions after the war.

Finally, despite the war, large-scale school expansion and literacy campaigns were carried out during the 1960s and 1970s, especially in North Vietnam, where promoting literacy was a central social goal of the regime (Ngo, 2004). Since school infrastructure was vulnerable to U.S. bombing, teachers and students dispersed into small groups to

Fig. 3. State investment (in per capita terms) 1976–1985, ratio of more heavily bombed (above median) to less heavily bombed (below median) provinces.

avoid strikes, and schools often had foxholes and helmets for students' protection during U.S. attacks (Duiker, 1995; Vien, 1981).

These results taken together are broadly in line with the predictions of the neoclassical growth framework: a loss of factor endowments due to war led to rapid catch-up growth and convergence back to the steady state, as proxied by performance in regions that suffered hardly at all from U.S. bombing. There is no evidence of a local poverty trap. The electricity infrastructure results are consistent with a vintage capital growth model, but we feel that distinguishing between the vintage and neoclassical models is less fundamental than our main finding of no adverse long-run local economic impacts, which provides evidence against poverty trap models. The most provocative result, and one that resonates with Davis and Weinstein (2002) and others in this emerging literature, is that the transition back to the economic steady state can be extremely rapid even after massive bombing and destruction.

6. Conclusion

We find no robust long-run impacts of U.S. bombing on local poverty rates, consumption levels, or population density in Vietnam over 25 years after the end of the "American War". Given that the bombing of Vietnam was the most intense bombing episode in world history, and that Vietnam was one of the world's poorest countries after the war, this is a surprising result from the point of view of poverty trap models of economic growth. This empirical result can be understood within the poverty trap model developed in this paper. We showed that, under the relatively weak condition that there is sufficient capital in the economy (or from foreign aid) postwar to lift at least initially, one district out of the poverty trap selective reallocation of capital by the central government towards poorer districts will generally prevent a national poverty trap from occurring. We then go on to find empirical evidence of substantial reallocation of Vietnamese government resources towards the regions that were more heavily bombed during the early 1980s. Most existing poverty trap models neglect inter-regional differences and the possibility of government intervention, and therefore exaggerate the theoretical plausibility of a poverty trap. Poverty traps thus seem unlikely to occur in practice as long as a reasonably capable government that seeks to promote economic growth is in power. Vietnam's rapid recovery from U.S. bombing – both in the bombed districts and in the country as a whole – strongly corroborates this view.

As discussed above, our empirical approach compares more heavily bombed areas to other areas and thus cannot directly estimate nationwide war effects on Vietnamese economic development. The theoretical model illustrates that inter-regional economic convergence could be due to the emergence of a national poverty trap, under extensive factor mobility across regions. However, the vigorous investment and growth observed in Vietnam during the postwar period does not appear consistent with the interpretation that Vietnam has been stuck in a national poverty trap due to the effects of wartime bombing. Nevertheless, the counterfactual – national Vietnamese economic outcomes in the absence of the war – is impossible to reconstruct. If the regions not greatly affected by the war assisted the more heavily bombed regions through postwar resource transfers, as the state investment data suggest, then differences between the more and less heavily bombed areas would be dampened but overall Vietnamese living standards could still have fallen. In that case, the actual aggregate effects of U.S. bombing on long-run Vietnamese economic performance would be more negative than our estimates imply. Yet the legacy of the war has clearly not prevented Vietnam from achieving rapid economic growth: Vietnamese growth in GDP per capita has recently been among the fastest in the world, at 6% per year between 1993 and 2003 (World Bank, 2004), following the reforms of the 1980s and 1990s. Our data indicate that the 1990s were a crucial period of economic convergence across regions.

Caution is called for in drawing broad lessons regarding war's impacts on economic growth in general. Unlike many other poor countries, postwar Vietnam benefited from relatively strong and centralized political institutions with the power to mobilize human and material resources in the reconstruction effort, and redistribute from richer to poorer districts. Countries with successful postwar recovery experiences (like Vietnam, Japan, and Germany) are also probably more likely to collect the sort of systematic economic data that make this study possible. This may lead to selection bias: war-torn countries where the economy and institutions have collapsed (e.g., Democratic Republic of Congo or Somalia) lack such data, preventing the estimation of any persistent local war impacts in those societies.

Vietnam also emerged successfully from war out of a long struggle for national liberation¹⁷ against foreign occupiers (principally the French and later the United States), an experience that fostered a strong sense of nationalism that could be mobilized in the postwar reconstruction. In contrast, the bulk of wars in the world today are internal civil conflicts, which may exacerbate political and social divisions and weaken national institutions rather than strengthen them. Some recent research suggests that the low-level civil conflict in the Basque region of Spain has significantly reduced economic growth there relative to neighboring regions (Abadie and Gardeazabal, 2003), for example. Collins and Margo (2004) find that the destructive U.S. race riots of the 1960s had lingering effects on the average income of local African-Americans up to twenty years later. The world's most conflict prone region today is sub-Saharan Africa, where state institutions are notoriously weak (Herbst, 2000). In such settings, postwar reconstruction may drag on far longer than in Vietnam (or in Japan, where postwar political institutions were also strong) leading to more persistent adverse war legacies. Due to the uniqueness of each society's institutions, politics, and history, in our view further empirical evidence accumulated across cases is needed before general claims about the effects of war on long-run economic performance can be made with confidence.

Acknowledgments

We are grateful to Vietnam Veterans of America Foundation (VVAFA), the Defense Security Cooperation Agency (DSCA), and the Technology Center for Bomb and Mine Disposal, Vietnam Ministry of Defense (BOMICO) for providing access to the U.S. military data, and in particular to Major Patrick Keane, Benjamin Reich, Michael Sheinkman, Bill Shaw, and Tom Smith. Pamela Jakiela, Marieke Kleemans, Melissa Knox, Khuyen Nguyen, Rachel Polimeni, Monika Shah and especially Paul Cathcart provided splendid research assistance. We are also grateful to Fred Brown, Jim Fearon, Raquel Fernandez, Scott Gartner, Steve Helfand, Chang-Tai Hsieh, Chad Jones, Dean Karlan, David Laitin, Adam Przeworski, Martin Ravallion, Debraj Ray, John Strauss and to numerous seminar participants at Harvard/MIT, ECARES-ULB, the 2005 ASSA Meetings, U.C. Riverside, U.C. Berkeley, University of British Columbia, the Pacific Development Conference, University of Michigan, Center for Global Development, Stanford University, the MacArthur Inequality Network, BREAD-CEPR Conference, Economic History Association Meetings, NYU, Cornell, and Yale, and two anonymous referees and the editor (Mark Rosenzweig), for useful comments.

Appendix A. Supplementary data

Supplementary data associated with this article can be found, in the online version, at [doi:10.1016/j.jdeveco.2010.07.004](https://doi.org/10.1016/j.jdeveco.2010.07.004).

¹⁷ The conflict in Vietnam was a combination of a war of national liberation and a civil conflict between the North and the South, but the postwar political rhetoric of the victorious North usually emphasized the former.
